ABSTRACT

Complex event processing (CEP) has become increasingly important for tracking and monitoring applications ranging from health care, supply chain management to surveillance. These monitoring applications submit complex event queries to track sequences of events that match a given pattern. As these systems mature the need for increasingly complex nested sequence queries arises, while the state-of-the-art CEP systems mostly focus on the execution of flat sequence queries only. In this paper, we now introduce an iterative execution strategy for nested CEP queries composed of sequence, negation, AND and OR operators. Lastly we have introduced the promising direction of applying selective caching of intermediate results to optimize the execution. Our experimental study using real-world stock trades evaluates the performance of our proposed iterative execution strategy for different query types.

H.4.2 [Information Systems]: Database Management Systems [Query Processing]

1. INTRODUCTION

Complex event processing (CEP) has become increasingly important in modern applications, ranging from supply chain management for RFID tracking to real-time intrusion detection [1, 2, 3]. CEP must be able to support sophisticated pattern matching on real-time event streams including the arbitrary nesting of sequence operators and the flexible use of negation in such nested sequences. For example, consider reporting contaminated medical equipments in a hospital [4, 5]. Let us assume that the tools for medical operations are RFID-tagged. The system monitors the histories of the equipment (such as, records of surgical usage, of washing, sharpening and disinfection). When a healthcare worker puts a box of surgical tools into a surgical table equipped with RFID readers, the computer would display approximate warnings such as “this tool must be disposed”. A query \( Q_1 = SEQ(Recycle \ r, \ Washing \ w, \ NOT \ SEQ(Sharpening \ s, \ Disinfection \ d, \ Checking \ c), \ Operating \ op) \) with the condition that \( [(ID) = \text{equality on ID}) \) and \( op.ins-type = \text{"surgery"} \) expresses this critical condition that after being recycled and washed, a surgery tool is being put back into use without first being sharpened, disinfected and then checked for quality assurance. Such complex sequence queries contain complex negation specifying the non-occurrence of composite event instances, such as negating the composite event of sharpened, disinfected and checked subsequences.

However, the state-of-the-art CEP in the literature including SASE [1] and ZStream [3] do not support such nested queries. Even though the Cayuga system [2] mentions composable queries, they assume the negation filter is only applied to a single primitive event type within the SEQ pattern. Our objective however is to allow the specification of negation within any level of the nested query as in the above example. While CEDR [6] allows application of negation over composite event types within their proposed language, the execution strategy for such nested queries is not discussed. In short, no processing mechanisms for nested complex negation of CEP queries have been discussed in the literature to date. In this work, we address this gap by designing an execution strategy specifically to handle nested CEP queries specified by the nested complex expression query language NEEL. The semantics of this language is presented in [7].

Our contributions in this paper include:

- We introduce an algebraic query plan for nested CEP queries expressed in NEEL [7].
- We design an iterative top-down execution strategy for NEEL queries that applies a window constraint tightening technique designed to correctly process nested sub-queries. Intermediate results are pushed up conservatively for delayed resolution when a child query can’t be fully answered locally for nested negation.
- We experimentally evaluate our proposed execution strategy on real data streams studying the impact of different properties of nested queries, including sub-query lengths and nesting levels.
- Lastly selective caching of intermediate results is introduced as a strategy for optimizing the execution. Caching is shown to be extremely effective at improving the query processing performance.

2. NESTED CEP QUERY MODEL

2.1 Event Model

An event instance is an occurrence of interest which can be either primitive or composite as further introduced below. A primitive

\[\text{NEEL} \text{ stands for Nested Complex Event Query Language.}\]
**event instance** denoted by a lower-case letter (e.g., 'e') is the smallest, atomic occurrence of interest in a system. $e_i.ts$ and $e_i.te$ denote the start and the end timestamp of an event instance $e_i$, respectively, with $e_i.ts \leq e_i.te$. For a primitive event instance $e_i$, $e_i.ts = e_i.te$. For simplicity, we use the subscript $i$ attached to a primitive instance $e$ to denote the timestamp $i$.

A composite event instance is composed of constituent primitive event instances $e = \{e_1, e_2, \ldots, e_n\}$. A composite event instance $e$ occurs over an interval. The start and end timestamps of $e$ are equal to min{$e_i.ts$ | $e_i$ in $e$} and max{$e_i.te$ | $e_i$ in $e$}, respectively.

An event type is denoted by a capital letter, say $E_i$. An event type $E_i$ describes a set of attributes that the event instances of this type share. An event type can be either a primitive or a composite event type [8]. Primitive event types are pre-defined in the application domain of interest. Composite event types are aggregated event types created by combining other primitive and/or composite event types. $e_i \in E_i$ denotes that $e_i$ is an instance of the type $E_i$. Suppose one of the attributes of $E_i$ is attr and $e_i \in E_j$, then we use $e_i$.attr to denote $e_i$'s value for that attribute.

### 2.2 The Nested Complex Pattern Query Language NEEL

We now briefly introduce the NEEL query language for specifying complex nested event pattern queries [1, 6, 9] as an extension of basic non-nested languages from the literature. NEEL supports the nesting of AND, OR, Negation and SEQ operators at any query nesting level as in Table 1.

#### Table 1: NEEL Query Language

A primitive event type $E_i$ itself is an event expression. If $E_1, E_2, \ldots, E_n$ are event expressions, an application of SEQ, AND and OR over these event expressions is again an event expression [8]. In other words, nesting of AND, OR, and SEQ operators is supported. SEQ in the PATTERN clause specifies a particular order in which the event instances of interest should occur. If there is a $!$ (NOT) symbol before an event expression in an operator, we say that the event expression marked by $!$ is to be negated. Event instances that satisfy the positive components with no events in the stream relative to this match satisfying the negative components are output. If several adjacent event types are marked by $!$ in a SEQ operator such as $\text{SEQ}(E_1, \ldots, E_3, \ldots, E_n)$, the query requires the non-existence of any $E_3$ and $E_n$ events in either order between $E_1$ and $E_n$ events within the input stream. In other words $\{e_1, E_3, e_4 \rightarrow e_1, e_3, e_4, e_5 \rightarrow e_1, e_3, e_4, e_6 \rightarrow e_1, e_3, e_4, \ldots\}$ are transformed into two $\text{SEQ}$ operators: $\text{SEQ}(\ldots)$, $\text{SEQ}(\ldots)$.

**2.3 Nested CEP Query Plan**

A query expressed by a NEEL specification is translated into a default algebraic query plan composed of the following algebraic operators: Window Sequence ($\text{WinSeq}$), Window Or ($\text{WinOr}$) and Window And ($\text{WinAnd}$). During query transformation, each expression in the event pattern is mapped to one operator node in the query plan. The same window $w$ is assigned to all operator nodes. WinSeq first extracts all matches to the positive components specified in the query, and then filters out events based on negative components as specified in the query. WinOr returns an event $e$ if $e$ matches any one of the event expressions specified in the WinOr operator. WinAnd computes the cross product of its positive components. For queries expressed by NEEL, predicates are placed into the respective algebra operators in the nested event expressions (see Section 2.2).

**3. NESTED CEP QUERY PROCESSING**

### 3.1 Execution of Individual Operators

For simplicity, we briefly review the implementation strategy of one of the operators, namely, the SEQ operator, while the others can be implemented in a similar fashion. We adopt the state-of-the-art stack-based strategy for SEQ execution [1, 10, 11]. We associate a stack with each event type in the query. Each received event instance is simply appended to the end of the stack of its type. Event instances are augmented with pointers ptr, to adjacent events to facilitate quick locating of related events in other stacks during result construction.
The arrival of an event instance \( e_m \) of the last event type \( E_m \) of a query \( q_i \) triggers the compute function of \( q_i \). The result construction is done by a depth first search along instance pointers \( p_{ri} \), rooted at that last arrived instance \( e_m \). All paths composed of edges “reachable” by these \( p_{ri} \) correspond to one matching event sequence returned for \( q_i \). When negative event types are specified in WinSeq, then during sequence construction any edges “reachable” from the root \( e_m \) are skipped if an instance of the negative event type is found in the corresponding stream position. Events that are outdated based on the window constraints are purged.

3.2 Iterative Nested Execution Strategy

Following the principle of nested query execution for SQL queries [12, 13, 14, 15], the outer query is evaluated first followed by its inner sub-queries. The results of the inner queries are passed up and joined with the results of the outer query. The main idea of our nested execution is about passing down more stringent window constraints from outer queries to inner queries. For every outer partial query result, a constraint window (see Figure 3) is passed down for processing each of its children sub-queries. These sub-queries compute results involving events within the substring constrained by the constraint window. Qualified result sequences of the inner operators are passed up to the parent operator and the outer operator then joins its own local results with that of its positive sub-queries. The outer sequence result is filtered if the result set of any of its negative sub-queries is not empty. We apply iterative execution until a final result sequence is produced by the root operator. Finally, the process repeats when the outer query consumes the next instance \( e \). We will discuss nested queries with negation and predicates in more detail in Sections 3.3 and 3.4, respectively.

### Figure 3: Algorithm to Compute Interval Constraints for an Inner Query \( q_i \): Given an Outer Partial Result \( r_j \)

#### 3.3 Processing Nested Queries with Negation

We now describe our approach of supporting negations in nested queries. In SASE [1, 11, 10], flat queries can have negations and they are dealt with using the timestamp comparison. More precisely, if a query has a negative \( A \) between positive \( B \) and \( C \) event types, they first evaluate the query without the negation, i.e., they compute all \( B-C \) pairs. Then for every result generated they check if an \( A \) event occurred between the qualified \( B \) and \( C \) events. If it occurs, such pairs are discarded. When two negative event types are adjacent to each other, their order does not matter. For example, \( \text{SEQ}(A, !B, !C, D) \) is equivalent to \( \text{SEQ}(A, !C, !B, D) \). That is, all \( (A, D) \) result pairs without any \( B \) and \( C \) events in between them would be returned. For negative event types at the end of a query, postponed sequence evaluation is applied. That is the execution is continued till the last negation as per our iterative strategy however results are not output. Instead at \( t \) the arrival of every new event we note the time stamp of the event and also check whether it is a triggering event for the last negative part of the query. If it is not a triggering event, based on the time stamp of the arriving event, some results from the buffer may be output and removed from the buffer. If it is a triggering event, the negative part of the query is executed and if it produces some partial results, the result buffers of the outer query are completely cleared. However if the negative ending part of the query does not produce any results, some results are output and removed from the result buffers based on the time stamp of the arriving event.

In our nested query model, a sub-query as a whole could also be negated. For example, \( \text{SEQ}(A, !B, !C, D) \). For each outer result of \( \text{SEQ}(A, D) \), we search for \( \text{AND}(B, C) \) results occurring between such \( A \) and \( D \) events. If none exist, then the outer \( \text{SEQ}(A, D) \) result is returned, otherwise it is filtered out.

We distinguish between the following positions in which the negation clause can occur.

- **Bound by Upper Query.** The existence of a negative event instance could be bounded by positive event instances in the direct upper queries. Examples of this category include \( \text{SEQ}(A,!B, C) \) and \( \text{SEQ}(A,\text{SEQ}(B, C), D) \). In the second query, negative \( C \) events are bounded by \( B \) and \( D \) events. \( B \) events that do not have any \( C \) events occurring after them and before \( D \) events are passed up to the upper query operator. All B events passed up will be joined with the outer \( \text{SEQ}(A, D) \) result to construct \( \text{SEQ}(A, \text{SEQ}(B, C), D) \) results.

- **Bound by Adjacent Query.** The existence of a negative event instance could be bounded by positive event instances of an adjacent sibling sub-query. Examples of this type include \( \text{SEQ}(A, \text{SEQ}(B, C), \text{SEQ}(D, E), F) \) or \( \text{SEQ}(A, !B, \text{SEQ}(C, D, E)) \). In this case, we apply a contextual delayed constraint technique. Namely, we conservatively pass up additional intermediate results as compared to the case described above. In \( \text{SEQ}(A, \text{SEQ}(B, C), \text{SEQ}(D, E), F) \), outer \( \text{SEQ}(A, F) \) results \( < a, f_j > \) are constructed. The constraint window for both children sub-queries \( \text{SEQ}(B, C) \) and \( \text{SEQ}(D, E) \) is \([a, t, f_j, ts]\). When processing the sub-query \( \text{SEQ}(B, C) \) within this constraint window, any event of type \( B \) should be passed up. We cannot filter out events of type \( B \) even though \( C \) events exist after it within its constraint window. The reason is that the right bound of the interval constraint of the query \( \text{SEQ}(B, C) \) is decided by the results of the query \( \text{SEQ}(D, E) \). We should not have a \( C \) event between a \( B \) or \( D \) event. However, it is not possible to know time stamps of \( D \) events while still processing the query \( \text{SEQ}(B, C) \). Hence the decision is postponed until the results of both the inner queries are returned to the outer query and then the filtering of results takes place based on the presence of \( C \) events.

#### 3.4 Processing Nested Queries with Predicates

The approach of handling sub-queries with correlated predicates is similar to the basic nested execution described above except that the join is not only based on timestamps but also on other predicates. Below, we list the different cases for predicate handling.

- **Local predicates.** Events are filtered based on predicate values before being stored in their stack. Query processing proceeds otherwise as explained above. For example, for the
query in Figure 2. Operating events where the instrument type is not equal to "surgery" will be filtered.

- Correlated predicates between inner and outer queries. Nested sub-queries may be correlated with their parent queries by means of predicates. In order to evaluate these queries with predicates, it is necessary to pass down attribute values to the children queries. For example, the query in Figure 2 requires events in the inner sub-queries have the same tool id as the outer match. For each outer SEQ(Recycle r, Disinfection d, Operating o) match, the tool id information for the operating instance is thus passed down to the children sub-queries. Inner query results involving events having the same tool id with the outer match are returned to the upper query.

3.5 Putting It All Together

At compile time, queries with negation bounded by an adjacent sub-query (as discussed in Section 3.3) are marked with label "delayed constraint". More specifically, if a query \( q \) is labeled as "delayed constraint", it not only needs to pass up potential \( q \) results, but also negative events are passed up as we can’t determine locally if they are in violation or not. The pseudo code of the nested execution algorithm is given in Figure 4. This function is called whenever a new event of the last positive event type in the outer query arrives. Figure 5 shows the algorithm for joining partial outer results with its children query results. As can be seen in Table 1, predicates on negative components are associated directly with the later and not with the operator a whole. They are thus only evaluated for those subqueries, for which the positive parent context match has already been established.

**Example 2.** Consider the query \( Q = SEQ(RECYCLE r, SEQ(WASH w, DRYING dr, SHARPENING s)) \) discharging d, SEQ(CHECKING c, RELABELING rl, OPERATING op). When event instances of types Recycle, Washing, Drying, Sharpening, Disinfection, Checking, Relabeling and Operating arrive, they are pushed into their respective stacks. The outer query is first evaluated for a given window size followed by the inner sub-query. The outer query construction is triggered by the arrival of Operating events which are of the rightmost positive event type in the root query. For every partial result \( \langle r, d, op, \rangle \) of the outer query SEQ(RECYCLE r, Disinfection d, Operating op), we compute the window constraints for its children queries. For details, see Figure 3. If we were to evaluate this query without predicates, all results for SEQ(WASHING w, Drying dr,Sharpening s) and SEQCHECKING c, RELABELING rl) would be constructed for events that occur within \( \langle r, d, op, \rangle \) and \( \langle d, op, ts \rangle \). Respectively. The outer operator joins with all results returned by its positive sub-query SEQ(CHECKING c, RELABELING rl). The outer result \( \langle r, d, op, ts \rangle \) fails if results of the negative child query SEQ(WASHING w, Drying dr, Sharpening s) exist. When evaluating \( Q \) with correlated predicates \( [id] \), the id is passed down from the outer query to the children sub-queries. Results involving events with the same id are constructed in the sub-queries.

4. PERFORMANCE EVALUATION

The objective of our evaluation is to verify if our strategy gives the correct results so that they can be used as a benchmark to compare alternate future methods against. We verify using various types of queries. We also make note of the execution time to test the effectiveness and practicability of our method.

4.1 Experimental Setup

We have implemented our proposed nested query processing framework within the scalable complex event processing engine ECube [16] written in Java. We ran the experiments on Intel Pentium IV CPU 2.8GHz with 4GB RAM. We evaluated our techniques using the real stock trades data from [17] with 10,000 event instances with a sliding window of size 10 ms. The data contained stock ticker, timestamp and price information.

**Figure 5: Result Evaluation**

4.2 Varying Children Subquery Number

The first experiment processed queries with increased number of sub-queries from 1 to 3 (Figure 6(a)). \( q_3 \) generates minimum results using maximum processing time among the three queries. \( q_1 \) has more sub-queries to process which thus consumes more CPU processing time. Also, more outer SEQ(MSFT,ORCL,IPIX,INTC) results are filtered in \( q_3 \) as more constraints exist as compared to the other queries. As expected, the computation time increases with the number of sub-queries because the probability of finding patterns decreases with an increasing number of event types.

**Increased Children Number:**

\( q_1 = SEQ(MSFT, SEQ(RIMM, AMAT), ORCL, IPIX, INTC); \)
\( q_2 = SEQ(MSFT, SEQ(RIMM, AMAT), ORCL, SEQ(YHOO, DELL), IPIX, INTC); \)
\( q_3 = SEQ(MSFT, SEQ(RIMM, AMAT), ORCL, SEQ(YHOO, DELL), IPIX, SEQ(CSCO, QQQ), INTC); \)

4.3 Varying Subquery Lengths

The second experiment processed the queries below with increased sub-query lengths (from 2 to 4) as depicted in Figure 6(b). We observed that \( q_6 \) generates the most number of results and uses the most CPU processing time among the three queries. This is because \( q_6 \) includes the sub-query with the longest length which consumes more computational time. As expected, less outer SEQ(MSFT, ORCL,INTC) results are filtered in \( q_6 \) as the existence of a longer pattern is relatively less likely as compared to the other queries with shorter patterns within the same input stream.

**Increased Query Length:**

\( q_4 = SEQ(MSFT, SEQ(RIMM, AMAT), ORCL, INTC); \)
\( q_5 = SEQ(MSFT, SEQ(RIMM, AMAT), YHOO, ORCL, INTC); \)
\( q_6 = SEQ(MSFT, SEQ(RIMM, AMAT, YHOO, DELL), ORCL, INTC); \)
4.4 Varying Subquery Nesting Levels

The third experiment processed the queries below with increased sub-query nesting levels as depicted in Figure 6(c). \( q_9 \) generates the most number of results and uses the most CPU processing time among the three queries. It is because \( q_9 \) includes the sub-query with the largest nesting levels which consumes more time to be computed. Less outer \( \text{SEQ(MSFT, ORCL, INTC)} \) results are filtered as it is relatively infrequent to have more events in levels occur in a sequence.

\[
\text{Increased Nesting Levels:} \\
q_7=\text{SEQ(MSFT,SEQ(IPIX,QQQ),ORCL,INTC)}; \\
q_8=\text{SEQ(MSFT,SEQ(IPIX,SEQ(RIMM,AMAT),QQQ),ORCL,INTC)}; \\
q_9=\text{SEQ(MSFT,SEQ(IPIX,SEQ(RIMM,SEQ(YHOO,DELL),AMAT),QQQ),ORCL,INTC)};
\]

5. NESTED QUERY OPTIMIZATION

Although the results of nested CEP queries obtained from the iterative execution strategy are correct, it produces results at a very slow rate which is attributed to the re-computation of the results for inner sub-queries every time an outer triggering event arrives which makes the processing expensive. To tackle this deficiency, we propose to cache and incrementally maintain the inner query results. Due to the sliding window, many intermediate results would continue to be valid from one sliding window to the next. Previously calculated results of the previous window should be cached and then be reused in the new window. In this paper we propose an optimization strategy of subexpression caching, focusing on positive nested subexpressions to explain the concept. We leave the refinement of this caching technique to support nested subqueries with negation or predicate correlation to our future work.

**Cache Design.**

We associate a cache with each query subexpression. Each cache is a triplet composed of the cache-interval, the output schema, and a container holding the set of cached results. The cache-interval is a semantic descriptor interval \([\text{leftbound}, \text{rightbound}]\) that indicates the time validity of the current cache content. Put differently, the cache is guaranteed to contain the full set of result tuples valid in the \([\text{leftbound}, \text{rightbound}]\) time range.

**Cache Usage.**

The same triggering event \( e \) may generate multiple results for each subexpression with overlapping intervals. To avoid re-computation of results occurring in the same interval, we first extract the time interval that covers the time period for all the possible results triggered by the same event \( e \) for a subexpression. Namely, the interval represents the minimum and maximum event time bounds for each subexpression. We will call this interval \( \text{query-interval} \). We will then check the \( \text{cache-interval} \). If there is an exact overlap between the two, we completely re-use the cached results. If however the \( \text{query-interval} \) is larger than the \( \text{cache-interval} \) we update the cache which we discuss in the next section.

**Cache Maintenance.**

Clearly, the cache content and associated semantic descriptor must be continuously maintained over time. We describe our strategies for cache maintenance below.

- **Interval-driven Cache Expansion.** We update the cache content when a new triggering event \( e_t \) arrives. That is, given a new triggering event instance \( e_{t_i} \), we calculate the new cache interval. For each subexpression, we compare the interval \([i, j]\) attached to the cache to the new interval \([m, n]\). By the way algorithm works, \( i = m \), since the left bound is maintained at the event with minimum timestamp.

  We compute the sub-query \( \text{SEQ}(E_{i+1}, \ldots, E_{i+n}) \) for all triggering events \( e_{i+j} \) between the interval \([j, n]\). New results are appended to the cache for each subexpression triggered by events.

- **Interval-driven Cache Reduction.** When a triggering event \( e_{t_i} \) arrives, events with timestamp less than \( e_{t_j} \) are purged from their stacks. Similarly, caching results involving events with timestamp less than \( e_{t_i} \) are deleted from the cache as the window constraint will be violated if these results join with the new triggering event \( e_{t_i} \) in the final result.

**Example 3.** In Figure 7, when the triggering event \( o_{26} \) arrives, it is inserted into the Operating stack and triggers execution. \([1, 15] \) and \([8, 26] \) are extracted time intervals for the subexpressions \( \text{SEQ(Washing, Drying, Sharpening)} \) and \( \text{SEQ(Checking, Relabeling)} \), respectively. \( \text{SEQ(Washing, Drying, Sharpening)} \) results are constructed based on all events that occurred during \([1, 15] \). Similarly, \( \text{SEQ(Checking, Relabeling)} \) events occurring during \([8, 26] \) are constructed and cached. When the new triggering event \( o_{30} \) arrives, we determine the interval for \( \text{SEQ(Washing, Drying, Sharpening)} \) is still \([1, 15] \). Thus the cache is still complete and thus we can reuse results in the cache. For subexpression \( \text{SEQ(Checking, Relabeling)} \), we find the new interval \([8, 30] \) overlaps with the previous interval \([8, 26] \). Conceptually, we could reuse the caching results related to \([8, 26] \) and we must compute the new additions to our cache. New \( \text{SEQ(Checking, Relabeling)} \) results are triggered by Relabeling events occurring between \([26, 30] \) such as \( r_{26} \). Assume the window size is 30. When \( o_{34} \) arrives, all caching results involving primitive events with time-stamp less than 4 expire. So \( w_2, d_6, s_7 >, w_2, d_3, s_7 > \) etc are deleted from the cache. The meta-data attached to the cache for \( \text{SEQ(Washing, Drying, Sharpening)} \) is updated from \([1, 15] \) to \([4, 15] \).

5.1 Evaluating Optimized Nested Execution

We process query \( q_9 \) comparing the optimized execution by the interval driven caching technique to the one without caching as in Figure 8. Caching helps in avoiding repeated computation for the subquery \( \text{SEQ(QQQ,AMAT,DELL)} \) as our results demonstrate. Clearly, we will have more or less gain with different reuse opportunities which may be caused by larger windows, more expensive sub-queries, etc.
7. CONCLUSION

In this paper, we have introduced a comprehensive strategy for processing nested CEP queries expressed using the NEEL query language [7]. In particular, we introduce the window constraint tightening technique to correctly and efficiently process nested subqueries by restricting the set of events to be considered for the match. Our proposed iterative execution strategy considers both nested negation as well as predicates within nested subexpressions. Lastly, an optimization technique based on caching of positive subexpressions is introduced. Our preliminary experimental results on real data streams demonstrate the complexity of the iterative execution of nested queries, and show the effectiveness of applying our proposed optimization strategy to tackle this problem. Based on these promising results, we intend in the future to further refine this caching strategy as well as develop alternative techniques for the optimization of nested CEP queries.

8. ACKNOWLEDGEMENTS

This work is supported by HP Labs Innovation Research Program and National Science Foundation under grants NSF 1018443 and NSF IIS 0917017, Turkish foundation under TUBITAK career award 109E194. We also thank Database System Research Group members at WPI for their valuable comments.
